Planetary cooling leads to solidification of any initially molten metallic core. Both S and Si are suggested to be present in the planet's core. We conducted high pressure experiments to investigate the partitioning behaviors of Si and S in the Fe-Si-S system from 15 to 25 GPa. The liquidus in this study is \(~150\) oC lower than that in the Fe-S binary system for same S concentration in liquid at same pressure. Almost all S prefers to partition into liquid, while the distribution of Si between solid and liquid depends on experimental P and T conditions at same time. We fitted the partition coefficient (KDSi) of Si between solid and liquid in correlation with experimental P, T and S concentration in liquid. At same pressure, the log(KDSi) is only linearly dependent on 1/T(K). The higher temperature (lower 1/T), the higher log(KDSi). With increase of pressure, the slopes of linear correlation between log(KDSi) and 1/T(K) will decrease. In other words, the higher pressure, the more Si will partition into solid. The S concentration in liquid has limited effect on Si partitioning between solid and liquid. Our experimental results can be directly applied to constrain the inner and outer core compositions of small terrestrial planetary (e.g. Mercury) and large planetary with a partially solidified core, a Si-rich solid inner core and a S-rich liquid out core are suggested according to our experimental results.
